7 Abstract

8 A fundamental issue in the design of a wireless sensor network is to devise mechanisms to make efficient use of its
9 energy, and thus, extend its lifetime. The information about the amount of available energy in each part of the network
10 is called the energy map and can be useful to increase the lifetime of the network. In this paper, we address the problem
11 of constructing the energy map of a wireless sensor network using prediction-based approach. Simulation results com-
12 pare the performance of a prediction-based approach with a naive one in which no prediction is used. Results show that
13 the prediction-based approach outperforms the naive in a variety of parameters. We also investigate the possibility of
14 sampling the energy information in some nodes in the network in order to diminish the number of energy information
15 packets. Results show that the use of sampling techniques produce more constant error curves.

19 1. Introduction

20 Wireless sensor networks are those in which
21 nodes are low-cost sensors that can communicate
22 with each other in a wireless manner, have limited
23 computing capability, and memory and operate
24 with limited battery power. These sensors can pro-
25 duce a measurable response to changes in physical
26 conditions, such as temperature or magnetic field.

The main goal of such networks is to perform dis- 27
tributed sensing tasks, particularly for applications 28
like environmental monitoring, smart spaces and 29
medical systems. These networks form a new kind 30
of ad hoc networks with a new set of characteris- 31
tics and challenges. 32

Unlike conventional wireless ad hoc networks, 33
a wireless sensor network potentially has hundreds 34
to thousands of nodes [11]. Sensors have to oper- 35
ate in noisy environments and higher densities 36
are required to achieve a good sensing resolution. 37
Therefore, in a sensor network, scalability is a cru- 38
cial factor. Different from nodes of a customary 39

40 ad hoc network, sensors are generally stationary
41 after deployment. Although nodes are static, these
42 networks still have dynamic network topology.
43 During periods of low activity, the network may
44 enter a dormant state in which many nodes go to
45 sleep to conserve energy. Also, nodes go out of
46 service when the energy of the battery runs out
47 or when a destructive event takes place [7]. An-
48 other characteristic of these networks is that sen-
49 sors have limited resources, such as limited
50 computing capability, memory and energy sup-
51 plies, and they must balance these restricted re-
52 sources to increase the lifetime of the network. In
53 addition, sensors will be battery powered and it
54 is often very difficult to change or recharge bat-
55 teries for these nodes. Therefore, in sensor networks,
56 we are interested in prolonging the lifetime of the
57 network and thus the energy conservation is one
58 of the most important aspects to be considered in
59 the design of these networks.

60 The information about the remaining available
61 energy in each part of the network is called the *en-*
62 *ergy map* and can aid in prolonging the lifetime of
63 the network. We can represent the energy map of a
64 sensor network as a gray level image as depicted in
65 Fig. 1, in which light shaded areas represent re-
66 gions with more remaining energy, and regions
67 short of energy are represented by dark shaded
68 areas. Using the energy map, a user may be able
69 to determine if any part of the network is about

Fig. 1. Example of an energy map of a wireless sensor network.

70 to suffer system failures in near future due to de-
71 pleted energy [13]. The knowledge of low-energy
72 areas can aid in incremental deployment of sensors
73 because additional sensors can be placed selec-
74 tively on those regions short of resources. The
75 choice of the best location for the monitoring node
76 can be made also based on the energy map. A
77 monitoring node is a special node responsible for
78 collecting information from sensor nodes. We
79 know that nodes near the monitoring node proba-
80 bly will spend more energy because they are used
81 more frequently to relay packets to the monitoring
82 node. Therefore, if we move the monitoring node
83 to areas with more remaining energy, we could
84 prolong the lifetime of the network.

85 A routing algorithm can make a better use of
86 the energy reserves if it chooses routes that use
87 nodes with more residual energy. The protocol
88 proposed in [5] is an example of a routing protocol
89 that could take advantage of the energy map. In
90 that work, it is described the trajectory based for-
91 warding protocol that is a new forwarding algo-
92 rithm suitable for routing packets along a
93 predefined curve. The idea is to embed the trajec-
94 tory in each packet, and let the intermediate nodes
95 make the forwarding decisions based on their dis-
96 tances from the desired trajectory. If this protocol
97 had the information about the energy map, the
98 trajectory could be planned in order to pass
99 through regions with more energy, thus preserving
100 or avoiding regions of the network with small re-
101 serves. Again, the goal here is to make better use
102 of the energy reserves to increase the lifetime of
103 the network.

104 Other possible applications that could take
105 advantage of the energy map are reconfiguration
106 algorithms, query processing and data fusion. In
107 fact, it is difficult to think of an application and/
108 or an algorithm that does not need to use an en-
109 ergy map. However, the naive approach to con-
110 struct the energy map, in which each node sends
111 periodically its available energy to the monitoring
112 node, would spend so much energy due to commu-
113 nications that probably the utility of the energy
114 information will not compensate the amount of
115 energy spent in this process. For that reason, bet-
116 ter energy-efficient techniques have to be devised
117 to construct the energy map.

118 In this paper, we focus on proposing mecha-
 119 nisms to predict the energy consumption of a sen-
 120 sor node to construct the energy map of a wireless
 121 sensor network. There are situations in which a
 122 node can predict its energy consumption based
 123 on its own past history. If a sensor can predict effi-
 124 ciently the amount of energy it will dissipate in the
 125 future, it will not be necessary to transmit fre-
 126 quently its available energy. This node can just
 127 send one message with its available energy and
 128 the parameters of the model that describes its en-
 129 ergy dissipation. With this information, the moni-
 130 toring node can update its local information about
 131 the available energy of this node. Clearly the effec-
 132 tiveness of this paradigm depends on the accuracy
 133 with which prediction models can be generated.
 134 We analyze the performance a probabilistic model,
 135 and compare it with a naive approach in which no
 136 prediction is used. Simulation results show that the
 137 use of the prediction-based model decreases the
 138 amount of energy necessary to construct the en-
 139 ergy map of wireless sensor networks. We also
 140 investigate the energy map construction using
 141 sampling techniques in a way that it is not neces-
 142 sary that all nodes send their energy information
 143 to the monitoring node. The energy dissipation
 144 rate of a node that did not send its energy informa-
 145 tion packet is estimated using the information re-
 146 ceived from its neighboring nodes. In situations
 147 in which neighboring nodes spend their energy
 148 similarly, we can save energy sampling the energy
 149 information. Results show that the use of sampling
 150 techniques produce more constant error curves,
 151 and can reduce the number of energy information
 152 packets needed to construct the energy map.

153 The rest of this paper is organized as follows. In
 154 Section 2, we briefly survey the related work. In
 155 Section 3, we describe an approach to construct
 156 a prediction-based energy map for wireless sensor
 157 networks. In Section 4, we present the energy dis-
 158 sipation used to describe the energy consumption
 159 in a sensor node. In Section 5, the prediction-based
 160 energy map construction is evaluated and com-
 161 pared with the naive approach. In Section 6, we
 162 analyze the possibilities of using sampling tech-
 163 niques to construct the energy map. Finally, in
 164 Section 7, we conclude giving directions for future
 165 work.

2. Related work

166

167 In [1,4,8,9], the authors explore issues related to
 168 the design of sensors to be as energy-efficient as
 169 possible. In particular, the WINS [1,8] and Pico-
 170 Radio [9] projects are seeking ways to integrate
 171 sensing, signal processing, and radio elements onto
 172 a single integrated circuit. The SmartDust project
 173 [4] aims to design millimeter-scale sensing and
 174 communicating nodes.

175 The energy efficiency is the primary concern in
 176 designing good media access control (MAC) pro-
 177 tocols for the wireless sensor networks. Another
 178 important attribute is scalability with respect to
 179 network size, node density and topology. A good
 180 MAC protocol should easily accommodate such
 181 network changes [12]. In addition, a lot of en-
 182 ergy-aware routing schemes have been proposed
 183 for wireless sensor networks. *Directed diffusion*,
 184 proposed in [3], is a new paradigm for communica-
 185 tion between sensor nodes. In this paradigm, the
 186 data are named using attribute-value pairs and
 187 data aggregation techniques are used to dynam-
 188 ically select the best path for the packets. This en-
 189 ables diffusion to achieve energy savings.

190 The work proposed in [13] obtains the energy
 191 map of sensor networks by using an aggregation-
 192 based approach. A sensor node only needs to re-
 193 port its local energy information when there is a
 194 significant energy level drop compared to the last
 195 time the node reported it. Energy information of
 196 neighbor nodes with similar available energy are
 197 aggregated to decrease the number of packets in
 198 the network. In [13], each node sends to the moni-
 199 toring node only its available energy, whereas in
 200 our work each node sends also the parameters of
 201 a model that tries to predict the energy consump-
 202 tion in the near future. With these parameters,
 203 the monitoring node can update locally its infor-
 204 mation about the current available energy at each
 205 node, decreasing the number of energy informa-
 206 tion packets in the network.

3. Prediction-based energy map

207

208 As described earlier, the knowledge about the
 209 amount of available energy in each part of the net-

work is an important information for sensor networks. A naive solution to construct the energy map is to program each node to send periodically its energy level to the monitoring node. As a sensor network may have lots of nodes with limited resources, the amount of energy spent by this approach is prohibitive. For that reason, better energy-efficient techniques have to be designed to gather the information about the available energy in each part of a sensor network.

In this work, we discuss the possibilities of constructing the energy map using a prediction-based approach. Basically, each node sends to the monitoring node the parameters of the model that describes its energy drop and the monitoring node uses this information to update locally the information about the available energy in each node. The motivation that guided us to this work is that if a node is able to predict the amount of energy it will spend, it can send this information to the monitoring node and no more energy information will be sent during the period that the model describes satisfactorily the energy dissipation. Thus, if a node can efficiently predict the amount of energy it will dissipate in the future time, we can save energy in the process of constructing the energy map of a sensor network.

In order to predict the dissipated energy, we studied a probabilistic model based on Markov chains. In this model, each sensor node can be modeled by a Markov chain. In this case, the node operation modes are represented by the states of a Markov chain and, if a sensor node has M operation modes, it is modeled by a Markov chain with M states. Using this model, at each time the node is in state i , there is some fixed probability, P_{ij} , that, in the next time-step,¹ it will be at state j . This probability can be represented by $P_{ij} = P\{X_{m+1} = j | X_m = i\}$. We can also define the n -step transition probability, $P_{ij}^{(n)}$, that a node currently in state i will be in state j after n additional transitions [10]: $P_{ij}^{(n)} = \sum_{k=1}^M P_{ik}^{(r)} P_{kj}^{(n-r)}$, for any value of $0 < r < n$.

With the knowledge of probabilities $P_{ij}^{(n)}$ for all nodes and the initial state of each node, it is possible to estimate some information about the network that can be useful in many tasks. In this work, we will use these probabilities to predict the energy drop of a sensor node. The first step to make this prediction is to calculate for how many time-steps a node will be in state s in the next T time-steps. If the node is in state i , the number of time-steps a node will stay in the state s can be calculated by: $\sum_{t=1}^T P_{is}^{(t)}$. Also, if E_s is the amount of energy dissipated by a node that remains one time-step in state s , and the node is currently in state i , then the expected amount of energy spent in the next T times, $E^T(i)$, is:

$$E^T(i) = \sum_{s=1}^M \left(\sum_{t=1}^T P_{is}^{(t)} \right) \times E_s. \quad (1)$$

Using the value $E^T(i)$, each node can calculate its energy dissipation rate (ΔE) for the next T time-steps. Each node then sends its available energy and its ΔE to the monitoring node. The monitoring node maintains an estimation for the dissipated energy at each node by decreasing the value ΔE periodically for the amount of remaining energy of each node. The better the estimation the node can do, the fewer the number of messages necessary to obtain the energy information and, thus, the fewer the amount of energy spent in the process of getting the energy map.

In this work, each node locally constructs its own transition probability matrix based only on its past history. In this case, P_{ij} will be the number of times a node was in state i and went to state j divided by the total number of time-steps the node was in state i . With this matrix, each node uses Eq. (1) to find its energy dissipation rate. If the prediction is good, this approach can save energy compared with the naive solution, because an energy information packet is not transmitted while the energy dissipation rate describes satisfactorily the energy drop in this node. In Section 5.4, we discuss the computational cost of this approach.

¹ A time-step is a small amount of time. We suppose that all state transitions occur at the beginning of any time-step.

296 **4. Energy dissipation model**

297 When simulation is used to analyze the per-
 298 formance of the energy map construction or any
 299 other energy related problem, we have to know
 300 how the energy dissipation happens in sensor
 301 nodes. To this end, in this work, we use the
 302 *state-based energy dissipation model* (SEDM) to
 303 model the energy drop in sensor nodes.

304 In the SEDM, nodes have various operation
 305 modes with different levels of activation and, thus,
 306 different levels of energy consumption. In this
 307 model, each node has four operation modes: *mode*
 308 1: sensing off and radio off; *mode 2*: sensing on and
 309 radio off; *mode 3*: sensing on and radio receiving;
 310 *mode 4*: sensing on and radio transmitting. The
 311 transitions between these modes are described by
 312 the diagram of Fig. 2. In that diagram, the opera-
 313 tion modes are represented by states 1, 2, 3 and 4.
 314 In addition, it was necessary to represent more two
 315 states 2' and 3'. The state i' also represents the
 316 operation mode i . The only difference is that when
 317 a node goes to state i , it always starts a timer,

318 whereas in state i' , it verifies if is there any event
 319 for it. In terms of energy consumption, state i is ex-
 320 actly the same as state i' . However, the behaviors
 321 of states i and i' are different.

322 The diagram of Fig. 2 shows the “commands”
 323 performed along the path (transition) between
 324 states. It means that whenever a node changes its
 325 current state it performs tests and actions until
 326 the new state is reached. The tests are: “rout-
 327 ing”—checks whether a message has to be routed;
 328 “sleep”—determines whether the node will sleep
 329 or not; “is there any event”—determines whether
 330 a new sensing event is present; “turn on radio”—
 331 determines whether the radio must be turned on
 332 or not; and “receiving”—determines whether the
 333 radio must receive or transmit. “Timer” is an ac-
 334 tion that starts a timer. The outcome of each test
 335 depends on a probabilistic parameter associated
 336 with the test. These transitions try to capture the
 337 behavior of a sensor node, specially in terms of en-
 338 ergy consumption.

339 It is important to point out that the tests are
 340 tied to the events. Clearly, the outcome of the test
 341 “is there any event” is always yes when an event is
 342 detected, and no otherwise. The “routing” test is
 343 yes when the node has to route some sensed infor-
 344 mation that happened in other part of the sensor
 345 field. Thus, this test is also influenced by the
 346 events. The “receiving” test depends also on the
 347 characteristics of the event. Its value is influenced
 348 by the degree of cooperation needed by the appli-
 349 cation. The “sensing” test is called only if there is
 350 no event in the area of the node. If no event hap-
 351 pens, this test will depend on the degree of cover-
 352 age needed by the application. The greater the
 353 value of *sleep-prob*, the smaller the coverage.

354 In the SEDM, two types of arrival models are
 355 simulated. In the first one, the event arrival is
 356 modeled by a Poisson process with parameter λ .
 357 This process is appropriate to model events that
 358 happen randomly and independently from each
 359 other. In the second model, the event arrival is
 360 modeled by a Pareto distribution. This distribution
 361 has a heavy-tailed property that implies that small
 362 occurrences are extremely common, whereas large
 363 instances represent very few occurrences. When a
 364 Pareto distribution is used to simulate the inter-ar-
 365 rival time of the events, they will happen in bursts.

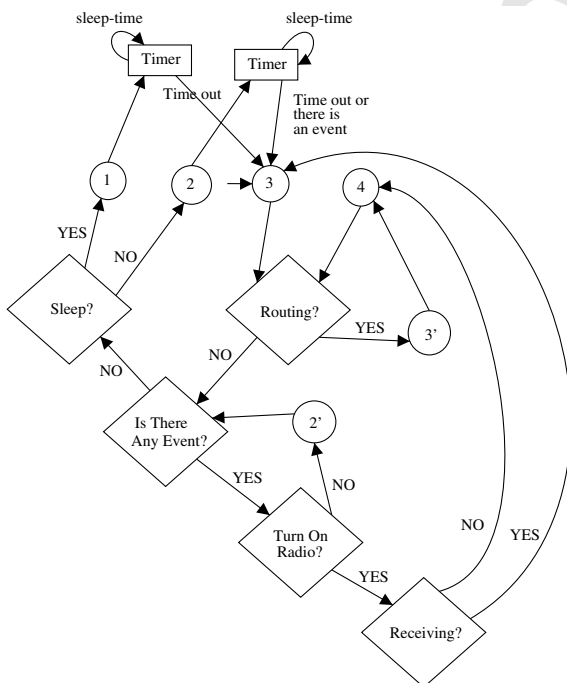

Fig. 2. Diagram of the state-based energy dissipation model.

366 This is because most of the inter-arrival time will
367 be small, meaning that we have lots of events.
368 However, the occurrence of large inter-arrival time
369 cannot be neglected, and thus it is possible to have
370 long periods of time without any event. The use of
371 Poisson process and Pareto distribution to model
372 the event arrival comes from the fact that these
373 are the most common models used in traffic gener-
374 ation problems.

375 When an event arrives, a position (X, Y) is ran-
376 domly chosen for it, and its behavior is described
377 by an event that is static and has a fixed size.
378 The radius of influence of an event is a random
379 variable uniformly distributed in $[event-radius-$
380 $min, event-radius-max]$ meters, and all nodes within
381 the circle of influence of an event will be affected
382 by it. Its duration is uniformly distributed in
383 $[event-duration-min, event-duration-max]$ seconds.

384 5. Simulation results

385 In this section, we present the simulation results
386 of the prediction-based approach to construct the
387 energy map and the naive solution. Section 5.1 de-
388 scribes the operation of the analyzed approaches.
389 Section 5.2 analyzes the performance of the ap-
390 proaches when the number of events is changed.
391 Finally, Section 5.3 shows the results when we
392 change the accuracy in which the energy maps
393 are constructed.

394 5.1. Basic operation

395 In order to analyze the performance of the pro-
396 posed schemes, we implemented the prediction-
397 based energy maps in the ns-2 simulator [6]. The
398 MAC protocol used was the default MAC proto-
399 col of ns-2. It is a simplified version of the
400 802.11 protocol. We use no particular routing
401 algorithm, but analyze the effect of the routing
402 process. The energy information packet was rou-
403 ted to the monitoring node using an aggregation
404 tree in which the monitoring node is the root. In
405 fact, the operating modes of a node were defined
406 based on the Berkeley's weC mote information.
407 The protocol stack used in the simulation does
408 not influence these values.

We implemented the Markov chain, in which
each node sends periodically to the monitoring
node its available energy, and its predicted energy
consumption rate, and compare it with the naive
one in which each node sends periodically to the
monitoring node only its available energy.

In this work, we consider a sensor network with
static and homogeneous nodes, replacement of
battery is unfeasible or impossible, and there is
only one static monitoring node with plenty of en-
ergy. Nodes are deployed randomly forming a
high-density network in a flat topology. Events
are static and their duration and radius of influ-
ence are randomly chosen. We simulate an event-
driven network in which sensors report informa-
tion only if an event of interest occurs. In this case,
the monitoring node is interested only in the
occurrence of a specific event or set of events.
The communication model among sensors is coop-
erative in the sense that is beyond the relay func-
tion needed for routing, and sensors
communicate with each other to disseminate infor-
mation related to the event. Besides, we used the
energy dissipation model presented in Section 4.

The accuracy required or the maximum error
acceptable in the energy map is controlled by the
parameter *threshold*. For instance, if its value is
3%, a node will send another energy information
to the monitoring node only when the error be-
tween the energy value predicted by the monitor-
ing node and the correct value is greater than
3%. Each node can locally determine this error
by just keeping the parameters of the last predic-
tion sent to the monitoring node. The parameter
threshold is used in both approaches to construct
the energy map. Thus, even in the naive solution,
another energy information packet is sent when
the error is greater than the parameter *threshold*.
Thus, in the naive approach, the *threshold* means
the drop in the last energy value sent to the mon-
itoring node.

In our simulations, the values of power con-
sumption for each state were calculated based on
information presented in [2]: Mode 1: 28.50 μ W,
Mode 2: 38.72 mW, Mode 3: 52.20 mW and Mode
4: 74.70 mW. These values will be used throughout
all simulations.

456 The numerical values chosen for the base case
 457 of our simulations can be seen in Table 1. Unless
 458 specified otherwise, these values are used in all
 459 simulations in this work. In this scenario, each
 460 node has an average of 23.6 neighbors. The mon-
 461 itoring node is positioned at the center of the field
 462 at position (25,25), all nodes are immobile, and
 463 can communicate with other nodes within their
 464 communication range. We assume that the moni-
 465 toring node knows the initial energy at each sensor.
 466 Before a node sends its first energy
 467 information packet, the monitoring node assumes
 468 that its power consumption is the average of the
 469 power consumption of all states. We also assume
 470 that nodes spend energy at the rate of 41.41 mW
 471 that is the average of power consumption of the
 472 four operation modes. In addition, the results of
 473 all simulations were obtained as an average of 33
 474 runs and they have a 95% confidence level.

Table 1
 Default values used in simulations

Parameters	Value
Number of nodes	100
Initial energy	100 J
Communication range	15 m
Sensor field size	$50 \times 50 \text{ m}^2$
<i>threshold</i>	3%
<i>event-duration-min</i>	5 s
<i>event-duration-max</i>	50 s
<i>event-radius-min</i>	5 m
<i>event-radius-max</i>	15 m

In Fig. 3a, we plot the correct value of the avail- 475
 able energy in a sensor node and the values found 476
 using the naive and Markov models during a simu- 477
 lation of 1000 s, when the event arrival is modeled 478
 by a Poisson process, and $\lambda = 0.001$. This figure 479
 shows that making the prediction using the 480

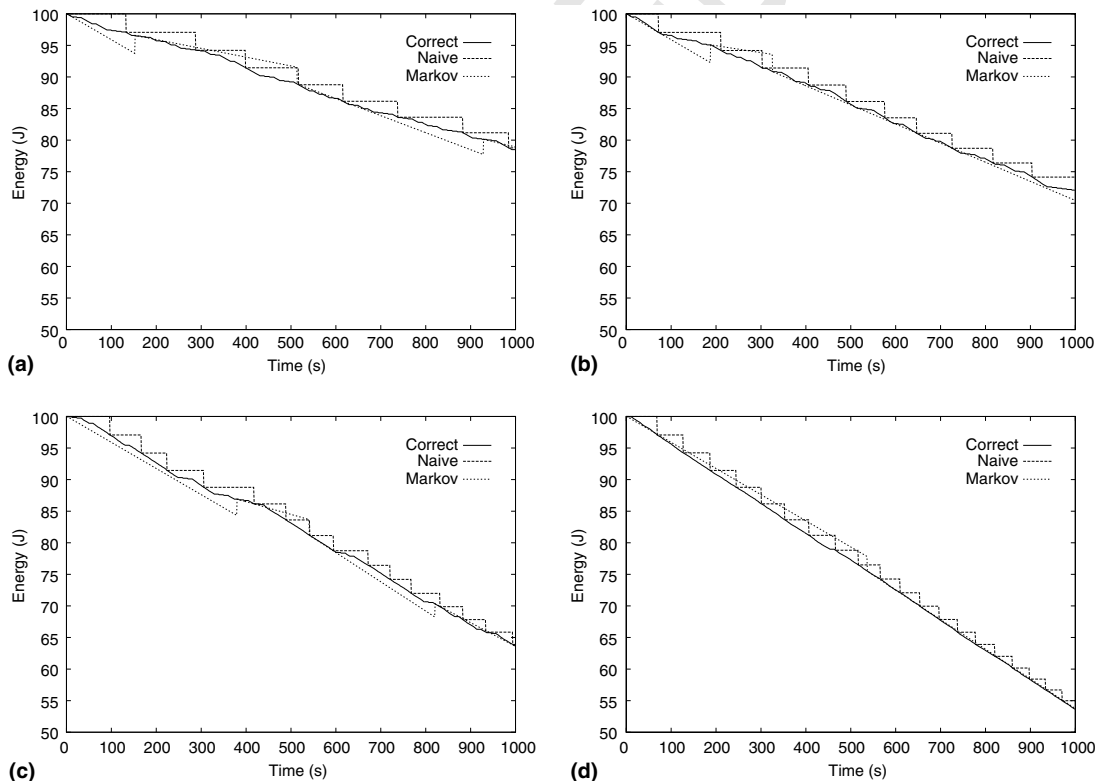

Fig. 3. The correct available energy in a sensor node and the values found using the naive and Markov models for different values of λ . (a) $\lambda = 0.001$, (b) $\lambda = 0.1$, (c) $\lambda = 0.5$, (d) $\lambda = 0.9$.

481 Markov model, during 1000s of simulation, this
 482 specific node had to send three energy information
 483 packets (at times 153, 514 and 929s) to keep its en-
 484 ergy information in the monitoring node with an
 485 error no greater than 3% (*threshold*). Using the na-
 486 ive approach, the node sent eight packets (at times
 487 133, 288, 399, 517, 616, 738, 883 and 985s) to keep
 488 its error smaller than 3%. It is important to point
 489 out that both approaches use the parameter *thresh-*
 490 *old* to decide when a new energy information pack-
 491 et has to be sent. Fig. 3b–d, shows what happens in
 492 the same sensor node when we change the number
 493 of events in the network. In Fig. 4, we plot the
 494 number of energy information packets this node
 495 had to send in simulations of Fig. 3. We can see
 496 that the number of packets sent when using the
 497 prediction-based model is less than when using
 498 the naive approach.

499 5.2. Changing the number of events

500 In this section, we analyze the performance of
 501 the energy map construction when we change the
 502 number of events in the network. Firstly, we use
 503 a Poisson process to model the event arrival, and
 504 the value of parameter λ is changed. Secondly, a
 505 Pareto distribution is used, and the parameter a
 506 is modified. In Fig. 5, we show the average number
 507 of events generated when parameters λ and a are
 508 changed.

509 Using the Poisson process to describe the event
 510 arrival, we executed the two approaches in the
 511 same scenario described above, during 1000s of

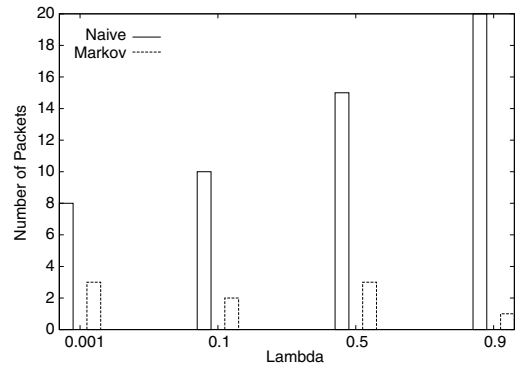

Fig. 4. Number of energy information packets the node of simulations of Fig. 3 had to send.

512 simulation. Fig. 6 shows the average number of en-
 513 ergy information packets that each node had to
 514 send to the monitoring node to construct an en-
 515 ergy map with an error no greater than 3%. We
 516 can see that, for all values of λ , the naive spends
 517 more energy information packets than the predic-
 518 tion-based approach. In addition, when the net-
 519 work becomes more active, the difference
 520 between the number of packets required by the na-
 521 ive and by the prediction-based approach is larger,
 522 meaning that the Markov is more scalable in rela-
 523 tion to the number of events in the network than
 524 the naive solution.

525 Nevertheless, the graph of Fig. 6 is not a fair
 526 way of comparing the two approaches because
 527 when a node, running the naive algorithm, has to
 528 send an energy information packet, the size of

Fig. 5. Average number of events when parameters λ and a are changed. (a) Poisson process, (b) Pareto distribution.

Fig. 6. Average number of packets for different values of λ , threshold = 3%.

529 the extra information required is only 2 bytes (its
530 available energy) and, in the Markov algorithm,
531 the overhead is of 4 bytes (its available energy
532 and its current power consumption). In order to

533 perform a fair comparison between the two ap-
534 proaches, we have to analyze the average number
535 of bytes that each node has to send when running
536 the naive and Markov algorithms. Thus, the met-
537 ric used to define energy efficiency will be the num-
538 ber of bytes transmitted. Fig. 7a compares the
539 average number of bytes that each node had to
540 send to the monitoring node without taking into
541 account the overhead of the packet header. In this
542 situation, we use piggybacking to send the energy
543 information. We can see that the number of bytes
544 that the naive has to send is even larger than the
545 number sent by the naive approach.

546 In Fig. 7b, we plot the total number of bytes
547 each node had to send considering that the packet
548 header is of size 30 bytes. In this situation, each
549 time a node has to send its energy information, it
550 will send 32 bytes (30 of header and 2 of payload)
551 in the naive algorithm, and 34 bytes (30 of header

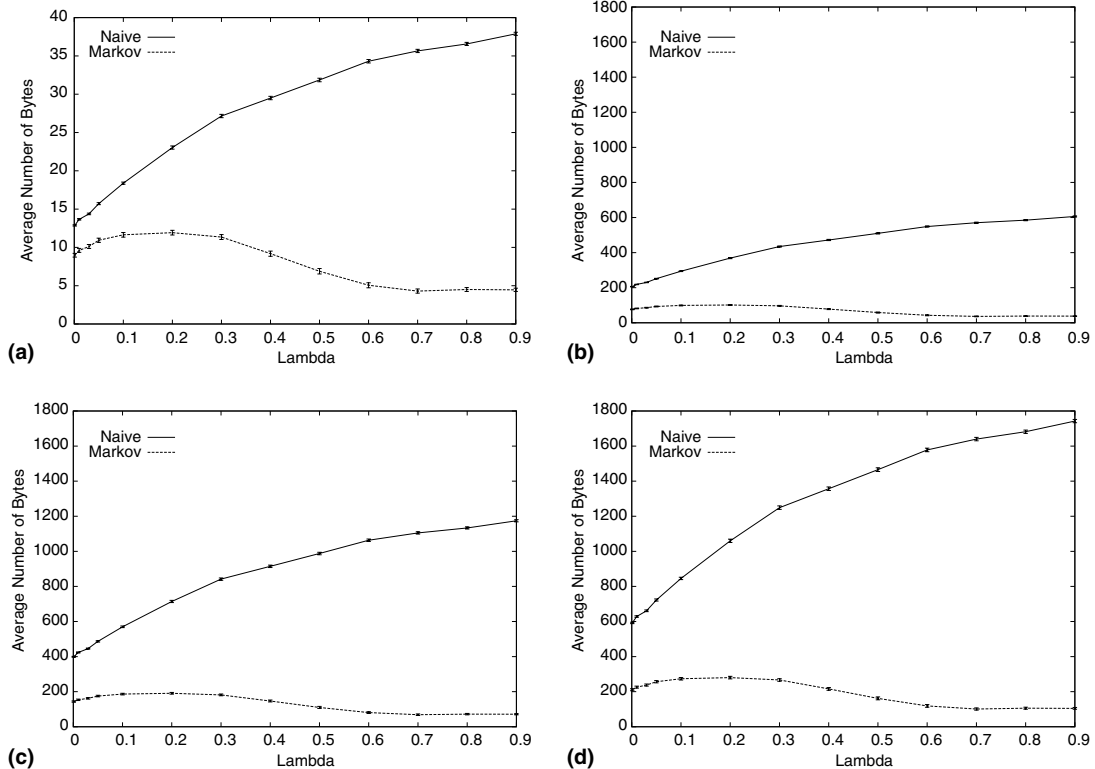

Fig. 7. Average number of bytes for different values of λ , threshold = 3%. (a) Using piggybacking to send the data, (b) packet header of 30 bytes, (c) packet header of 60 bytes, (d) packet header of 90 bytes.

552 and 4 of payload) in the Markov. We can see that,
 553 in this case, the Markov is still the best of the two.
 554 Fig. 7c and d shows what happens when the packet
 555 header is of size 60 and 90 bytes, respectively. In all
 556 situations, the Markov approach is still better than
 557 the naive for all values of packet size.

558 In the next simulations, we use the Pareto distri-
 559 bution to describe the behavior of the event arrival
 560 in the network. Fig. 8 shows the average number
 561 of energy information packets each node had to
 562 send to the monitoring node. In Fig. 9 we analyze
 563 the number of bytes transmitted by each approach.

564 We can observe that the results of the Pareto
 565 distribution are similar to the Poisson process.
 566 Observing these graphs and the average number
 567 of events generated in each model (Fig. 5), we
 568 can say that the event arrival model does not influ-
 569 ence the performance of the prediction-based en-
 570 ergy map construction. In fact, a uniformly

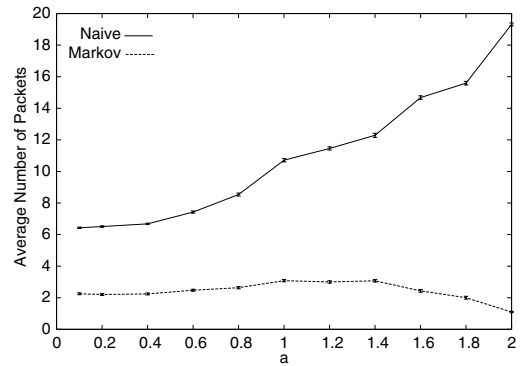

Fig. 8. Average number of packets for different values of α , threshold = 3%.

571 distributed event arrival model tends to be slightly
 572 easier to be predicted because the future is more
 573 likely the present. However, this trend is faintly,

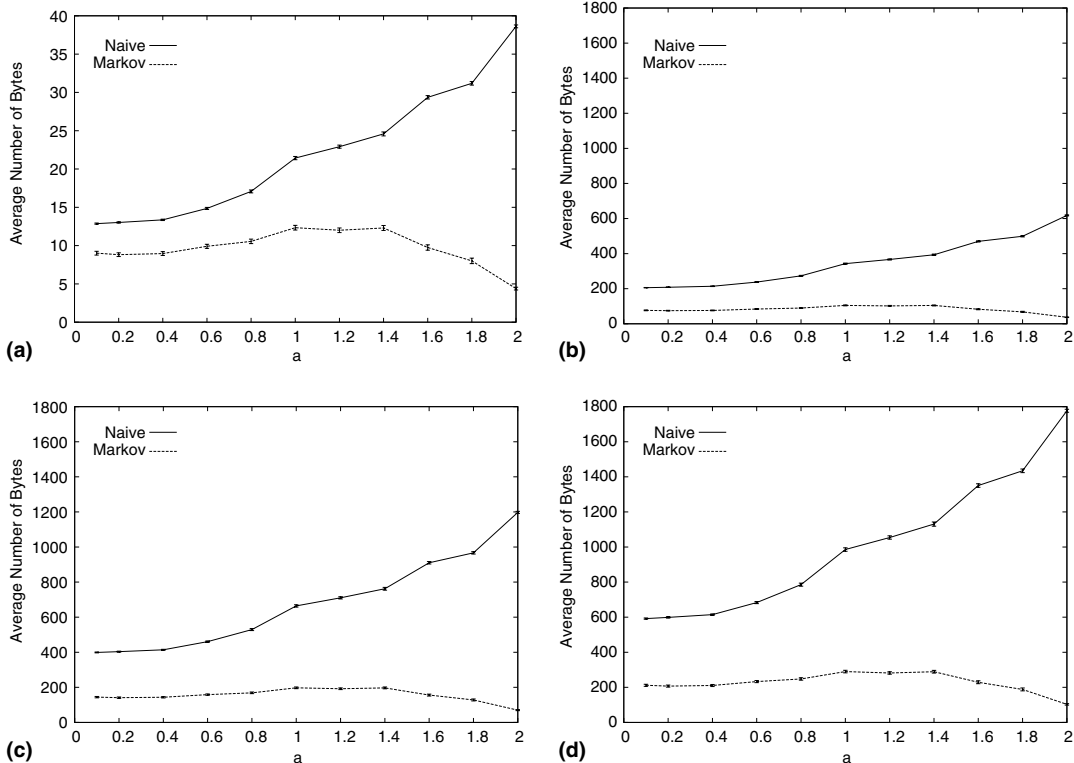

Fig. 9. Average number of bytes for different values of α , threshold = 3%. (a) Using piggybacking to send the data, (b) packet header of 30 bytes, (c) packet header of 60 bytes, (d) packet header of 90 bytes.

574 and probably will be more observed in long time
575 simulations.

576 Notice that the prediction approach has a better
577 behavior when the number of events is big or
578 small. The worst case of this approach happens
579 for medium values of number of events. Using
580 the Poisson model, the worst case for the Markov
581 is $\lambda = 0.2$, and using Pareto, the worst is when
582 $a = 1.4$. This means that the fact of having more
583 events does not make the problem of prediction
584 more difficult. The more difficult situations for
585 the prediction approach happens when there is a
586 medium number of events. In the naive approach,
587 the spent energy is proportional to the number of
588 events since a node will have to send energy infor-
589 mation packets more often to the monitoring
590 node. Thus, the prediction-based approach scales
591 well when the number of events increases or, the
592 power of making prediction is improved when
593 the activity of the network increases.

594 5.3. Changing the energy map precision

595 In order to analyze the performance of the ap-
596 proaches in situations where it is necessary an en-
597 ergy map with a very low error (small *threshold*),
598 and also when we can tolerate a greater error
599 (big *threshold*), we changed the value of the param-
600 eter *threshold*. We ran the naive and Markov algo-
601 rithms for 100 nodes in the same scenario
602 described above, using a Poisson process to model
603 the event arrival. In these simulations, we analyze
604 the worst case for the Markov model that is when
605 the value of λ is 0.2.

606 Fig. 10 shows the average number of energy
607 information packets that each node had to send
608 to the monitoring node, during a simulation of
609 1000s, to construct an energy map with an error
610 no greater than the corresponding *threshold*. We
611 can see that, the Markov approach is better than
612 the naive for all values of *threshold*. Even when
613 we compare the number of bytes instead of the
614 number of packets, the Markov is better than the
615 naive solution. This comparison is shown in Fig.
616 11.

617 Fig. 11a compares the average number of bytes
618 that each node had to send to the monitoring node
619 when piggybacking is used to send the energy

Fig. 10. Average number of packets for different values of *threshold*, $\lambda = 0.2$.

information. Fig. 11b–d, show the average number of bytes when the packet header has 30, 60 and 90 bytes, respectively. We can see that, for all values of *threshold* analyzed, the Markov model was more energy-efficient than the naive. Recall that results shown in this section represent the worst case for the Markov model. For all other values of λ , the difference, in terms of energy consumption, between this model and the naive is even higher.

5.4. Computational cost of the Markov model

In this section, we analyze the number of operations executed by each sensor node in order to construct the energy map using the Markov model. To construct the prediction-based energy map, each node has to maintain its own probability matrix. This matrix is updated at each time-step of the simulation to keep track of its operation modes. Besides, at each time-step the node verifies if the error in the energy information is greater than the parameter threshold. The number of sums/subtractions, multiplications/divisions, comparisons and assignments performed to execute these tasks is 3, 2, 1 and 3, respectively.

When the error in the energy information reaches the parameter threshold, another energy information packet is sent. In this case, a new value of $E^T(i)$ has to be calculated. The total number of operations executed in this calculation depends on the value of T and on the number of energy

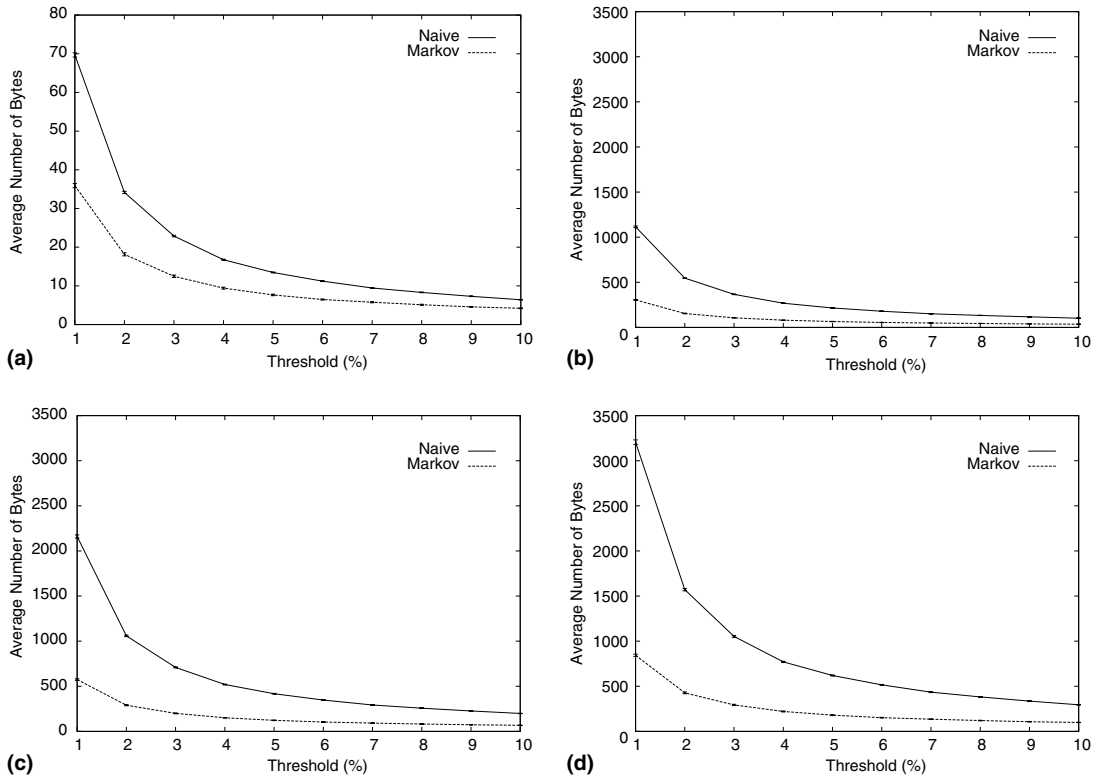

Fig. 11. Average number of bytes for different values of *threshold*, $\lambda = 0.2$. (a) Using piggybacking to send data, (b) packet header of 30 bytes, (c) packet header of 60 bytes, (d) packet header of 90 bytes.

650 information packets sent. In our simulations we
 651 used $T = 5$. Table 2 shows the average number
 652 of operations executed at each time-step of simulation
 653 for some values of T . In the analysis of the
 654 best and worst cases, we use the simulation results
 655 presented in Section 5.2. In the best case, we consider
 656 that only one energy information packet is sent during
 657 1000s of simulation. In the calculation of the worst case
 658 scenario, we use the results of
 659 Figs. 6 and 8. These results show that, in the worst
 660 case, the Markov prediction sends less than four
 661 energy information packets during 1000s of simulation.
 662 Thus, the best case was obtained considering that an
 663 energy information packet is sent during 1000s of
 664 simulation and, in the worst case, four energy
 665 information packets are sent during the same amount
 666 of time.

6. Energy map construction using sampling technique 667 668

669 In this section, we analyze the use of sampling
 670 techniques to construct the energy map. In some
 671 sensing applications, neighboring nodes tend to
 672 spend their energy similarly. In such situations,
 673 we can use sampling techniques in a way that it
 674 is not necessary that all nodes send their energy
 675 information to the monitoring node. The energy
 676 dissipation rate of a node that did not send its
 677 energy information packet is estimated using the
 678 information received from its neighboring nodes.
 679 Simulation results compare the performance of a
 680 sampling approach with the Markov model presented
 681 in Section 3. Results show that the use of
 682 sampling techniques produce more constant error
 683 curves, and that these approaches can reduce the

Table 2

684 number of energy information packets needed to
685 construct the energy map.

686 This section is organized as follows. Section 6.1
687 presents a sampling model used to determine when
688 each node will send its energy information packet,
689 and how the energy consumption rate of a node
690 that did not send its energy information is esti-
691 mated by the monitoring node. Section 6.2 pre-
692 sents simulation results that compare the
693 sampling technique proposed in this section with
694 the original Markov model.

695 6.1. Sampling model

696 In the original Markov model, when the error
697 between the energy in a sensor node and the corre-
698 sponding value in the monitoring node is greater
699 than a *threshold*, an energy information packet is
700 always sent to the monitoring node. We define
701 the sampling model in such a way that, when the
702 error reaches the value of *threshold*, an energy
703 information packet is sent with probability p .
704 Using this idea, we can consider the original Mar-
705 kov a special case of the sampling model in which
706 the value of p is always 1.

707 The choice of the parameter *threshold* has to be
708 done locally without any communication between
709 sensor nodes. The value of p can be defined stati-
710 cally or dynamically. In both cases, a constant d ,
711 that represents the sampling degree, is defined.
712 This constant determines the initial value of prob-
713 ability p . In the static sampling, p is always equals

714 to d during all simulation. In the dynamic sam-
715 pling, its value increases whenever the error
716 reaches the *threshold* and no energy packet is sent.
717 Thus, the larger the error, the larger the value of p
718 and, consequently, the larger the probability of a
719 node to send its energy information packet. To this
720 end, we define probability p according to the fol-
721 lowing equation:

$$p = d + (1 - d) \times \left(1 - \frac{k}{k + n}\right) \quad (2)$$

722 where k determines the speed that probability p
723 reaches 1. For small values of k , p reaches asymp-
724 totically 1 faster. Furthermore, n is the number of
725 times the error reached the *threshold*. Notice that
726 the updating process of p is memory-less. When
727 a new energy information packet is sent, n goes
728 to zero and p is restored to its initial value (the
729 value of d as mentioned above). Fig. 12 illustrates the
730 value of p for different values of k when $d = 0.4$.
731

732 The sampling technique described in Eq. (2)
733 diminishes the number of packets used in the
734 map construction, and increases its error. To min-
735 imize the error, the monitoring node has to esti-
736 mate the energy consumption rate of nodes that
737 did not send their energy information packet. We
738 suppose that a node and its neighbors spend en-
739 ergy in a similar way. When the monitoring node
740 receives an energy packet, it uses interpolation to
741 update the energy consumption rate of its neigh-
742 boring nodes of the received packet. This update
743 considers the last consumption rate sent by the
744

Fig. 12. Probability p for $d = 0.4$.

746 node, named c_{node} , and the average energy con-
 747 sumption rate of its neighboring nodes that sent
 748 their energy information packet after this node
 749 sent the packet, named $c_{\text{neighbors}}$. The trade-off be-
 750 tween this two pieces of information is defined by
 751 Eq. (3) that determines the weight of the energy
 752 consumption rate of the neighboring nodes. In this
 753 equation, $n_{\text{interpolations}}$ represents the number of
 754 interpolations executed for the node.

$$p_{\text{neighbors}} = (1-d) + d \times \left(1 - \frac{k}{k + n_{\text{interpolations}}}\right) \quad (3)$$

758 Therefore, when the monitoring node receives
 759 an energy information packet, it updates the con-
 760 sumption rate of all neighboring nodes of this
 761 packet. This new consumption rate, named $c_{\text{estimated}}$,
 762 is defined by Eq. (4).

$$c_{\text{estimated}} = c_{\text{neighbors}} \times p_{\text{neighbors}} + c_{\text{node}} \times (1 - p_{\text{neighbors}}) \quad (4)$$

766 The goal of Eq. (4) is to update the node con-
 767 sumption rate with a more recent information re-
 768 ceived from its neighbors. The use of the value
 769 $n_{\text{interpolations}}$ in Eq. (3) is justified because, as the
 770 node information is estimated several times in
 771 the monitoring node, the last energy packet infor-
 772 mation values loose significance. Consequently,
 773 the more recently the energy packet is, the
 774 more expressive its value in the map. The value
 775 of $p_{\text{neighbors}}$ depends also on the sampling degree.
 776 The smaller this value is, the greater the value of
 777 $p_{\text{neighbors}}$. It is important to point out that Eq. (3)
 778 is only used in the dynamic approach. In the static
 779 model, the same equation is $p_{\text{neighbors}} = (1-d)$.

780 In some situations, when sampling is used, the
 781 error from the point of view of the node is smaller
 782 than from the point of view of the monitoring
 783 node. This happens when an energy information
 784 packet has to be sent and, due to the sampling
 785 probability p , it is not. In this case, from the point
 786 of view of the node, the error is zero and the value
 787 of p is increased, whereas from the point of view of
 788 the monitoring node the error continues increas-
 789 ing. However, the total error is evaluated by using
 790 the point of view of the monitoring node.

6.2. Simulation results

792 We implemented the energy map construction
 793 using sampling in the ns-2 simulator [6] and com-
 794 pared it with the original Markov model. Unless

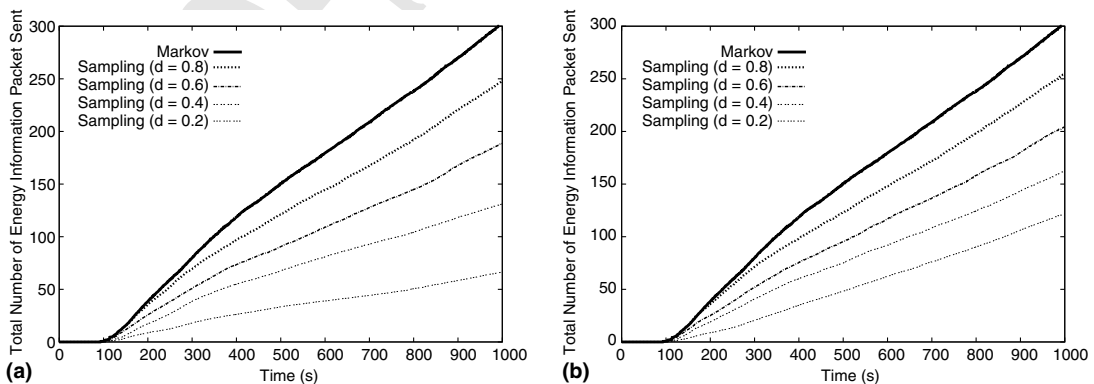

Fig. 13. Number of energy packets sent using the static and dynamic sampling approaches. (a) Static sampling, (b) dynamic Sampling.

795 specified otherwise, the default values used in
796 simulations of this section are the same defined
797 in Section 5.1. Besides, in all simulations of this
798 section, the Poisson process with $\lambda = 0.2$ is used
799 to model the event arrival.

800 Our goal, in the first simulation, is to analyze
801 the total number of energy information packets
802 sent using the original Markov and the sampling
803 technique for the following values of d : 0.2, 0.4,
804 0.6 and 0.8. Fig. 13 shows these results for the sta-
805 tic and dynamic sampling models. As it was ex-
806 pected, in all simulations, the total number of
807 energy information packets sent by sampling tech-
808 niques was less than the amount sent by the Mar-
809 kov. We can observe that, the smaller the sampling
810 degree is, the lower the total number of energy
811 packets sent. In the static approach, this value is
812 probabilistically equals to the sampling degree
813 multiplied by the total number of energy packets
814 sent by Markov. In the dynamic approach, the

815 number of packets sent is greater than this multi-
816 plication, because the probability p of sending a
817 packet increases whenever the node reaches the va-
818 lue of *threshold*, and its energy information is not
819 sent. The speed of this increase is determined by
820 the value of k . In all simulations, we use $k = 1$. Ta-
821 ble 3 shows the number of energy information
822 packets sent at the end of simulation for both
823 models.

Table 3

Total number of energy packets sent using the static and dynamic sampling approaches

Model	Static approach	Dynamic approach
Sampling ($d = 0.2$)	66	122
Sampling ($d = 0.4$)	132	162
Sampling ($d = 0.6$)	189	204
Sampling ($d = 0.8$)	248	255
Markov	303	

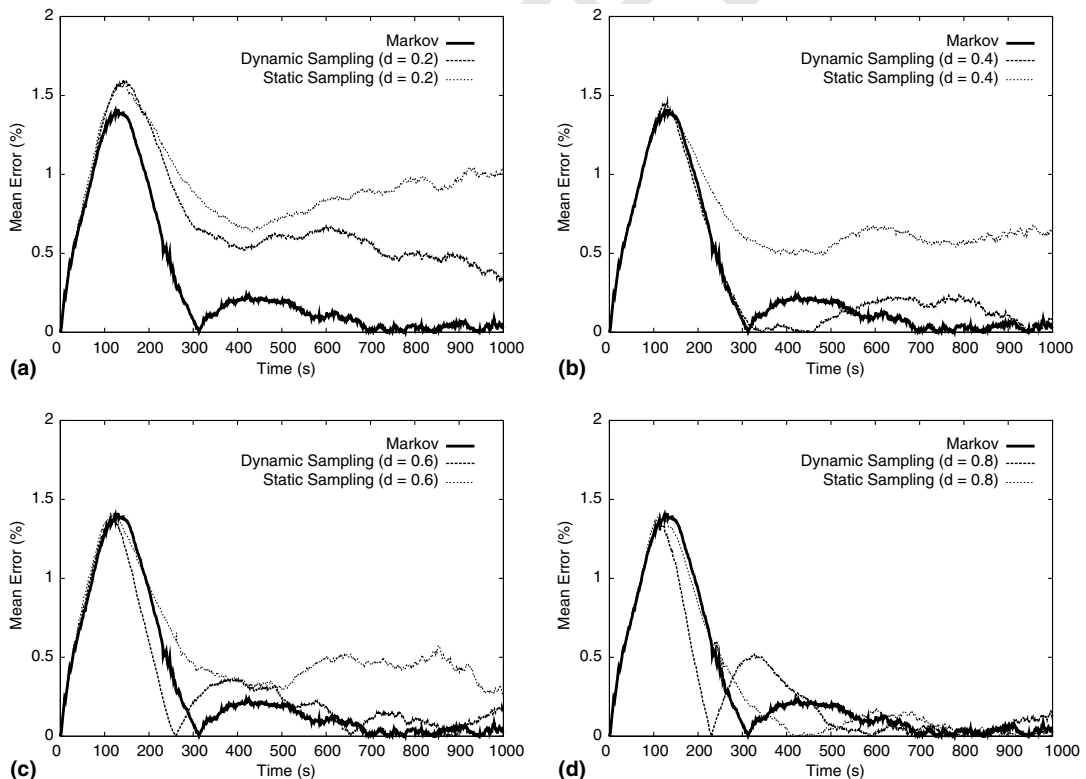

Fig. 14. Error using the static and dynamic sampling approaches. (a) $d = 0.2$, (b) $d = 0.4$, (c) $d = 0.6$, (d) $d = 0.8$.

824 Fig. 14 shows the average error in percentage
 825 for a simulation of 1000s. We verify that the Mar-
 826 kov has the smallest error, followed by the dy-
 827 namic and static approaches, respectively. This is
 828 due to the total number of energy information
 829 packets sent in each approach. An interesting
 830 point when comparing Figs. 13 and 14 is that the
 831 dynamic approach has a better performance than
 832 the static one. For instance, the dynamic model
 833 using $d=0.2$ sends 122 packets, while the static
 834 using $d=0.4$ sends 132. However, the errors of
 835 both approaches are very similar. When we com-
 836 pare the dynamic model using $d=0.4$ and
 837 $d=0.6$ with the static one using $d=0.6$ and
 838 $d=0.8$, respectively, we verify that the former
 839 sends less energy packets, and has smaller errors.
 840 The advantage of the dynamic model is due to
 841 the increase in the probability p when a node do
 842 not send an energy packet.

843 Our next goal is to compare sampling techni-
 844 ques with and without the interpolation defined
 845 in Eq. (4). Fig. 15 shows that the greater the
 846 sampling degree, the smaller the advantage of using
 847 the interpolation phase. This is expected because
 848 when the sampling degree increases, the number
 849 of energy information packets received by the
 850 monitoring node also increases. As the interpola-
 851 tion does not have any influence in the sampling
 852 phase, the number of energy information packets
 853 is exactly the same in both curves of the same fig-
 854 ure. It is important to point out that, in our simu-
 855 lation model, failures are not considered.
 856 Therefore, if failures are considered, the interpola-
 857 tion phase can improve the map quality because
 858 lost information can be estimated from informa-
 859 tion of neighboring nodes.

860 As observed in Section 5.3, one way to diminish
 861 the number of energy information packets needed

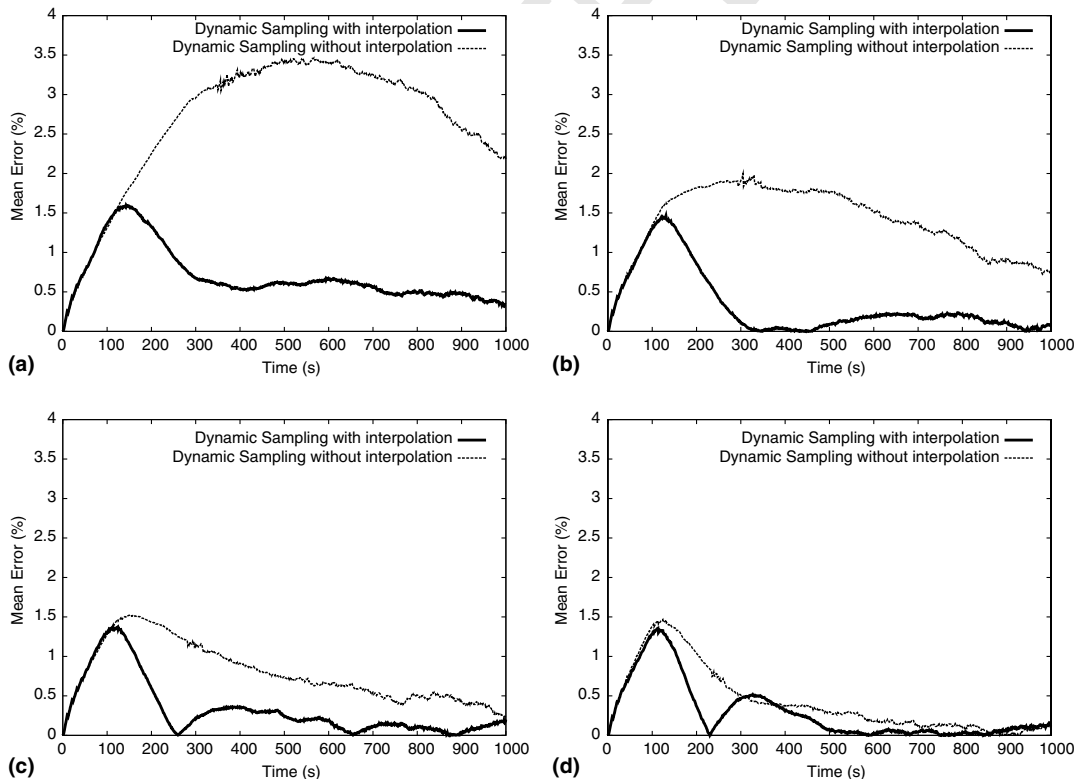

Fig. 15. The influence of the interpolation phase in sampling techniques. (a) $d=0.2$, (b) $d=0.4$, (c) $d=0.6$, (d) $d=0.8$.

862 to construct the map is to increase the value of the
 863 parameter *threshold*. Our next goal is to compare
 864 the Markov using a large value of *threshold* with
 865 sampling techniques. When we increase the value
 866 of the parameter *threshold* in the Markov model,
 867 all nodes send their energy information less fre-
 868 quently. In sampling models, few nodes send their
 869 energy information more frequently. Fig. 16 com-
 870 pares these two approaches. In Fig. 16a and b, we
 871 compare the Markov using *threshold* = 5% with
 872 the sampling model using *threshold* = 3% and
 873 $d = 0.5$ and 0.6 . Fig. 16c and d shows the Markov
 874 with *threshold* = 7% and the sampling with thresh-
 875 old = 3% and $d = 0.3$ and 0.4 . Fig. 16a and c
 876 shows the total number of energy packets sent dur-
 877 ing all simulation, and Fig. 16b and d shows the
 878 mean error in percentage. We can see that, for sim-
 879 ilar number of energy packets, the error of the

880 sampling model is smaller than the one of the Mar- 880
 881 kov. Fig. 16a and c shows that, at the beginning of 881
 882 simulation, the number of packets sent by Markov 882
 883 is smaller, and, thus, its error is bigger than the er- 883
 884 ror of sampling models. This happens because the 884
 885 value of *threshold* delays the sending of the energy 885
 886 packets in the Markov model. Therefore, the sam- 886
 887 pling model produces more constant error curves 887
 888 than the original Markov. This is the greatest 888
 889 advantage of sampling models over the original 889
 Markov.

7. Conclusions and future directions 891

892 In this work, we have studied the problem of 892
 893 constructing the energy map of wireless sensor net- 893
 894 works using prediction-based approach. In this 894

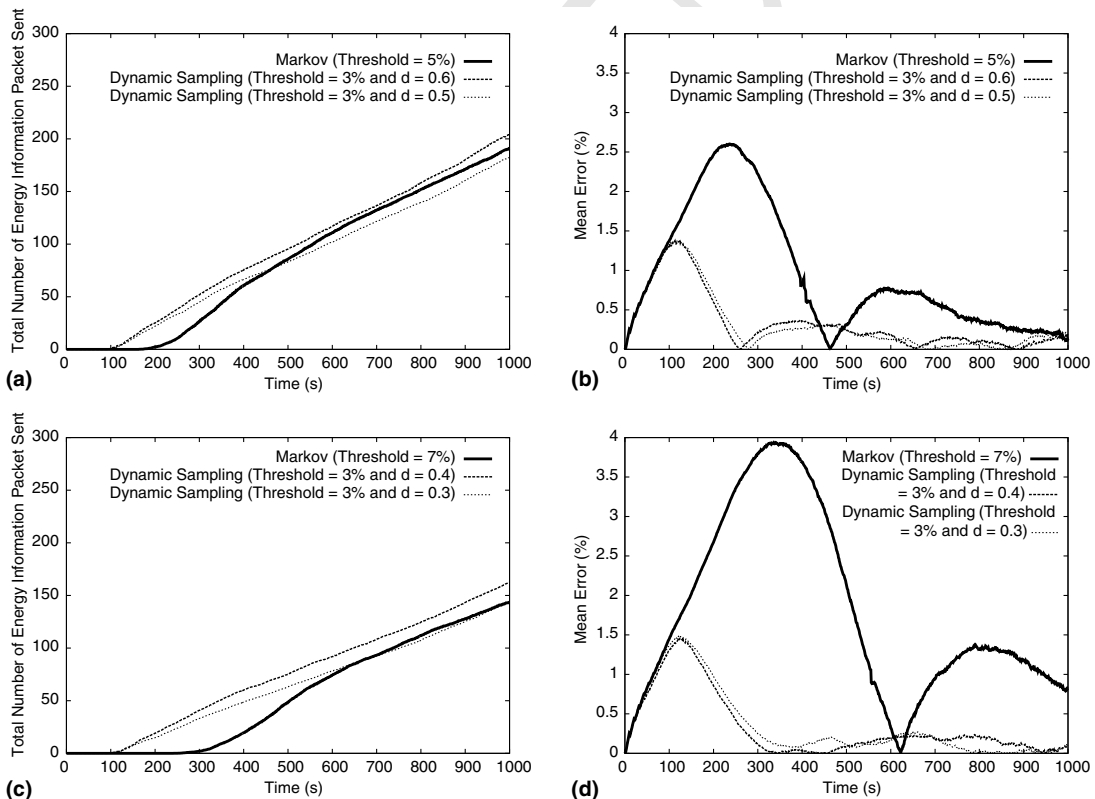

Fig. 16. Sampling models vs. original Markov using different values of *threshold*. (a) Energy packet number, (b) average percentage error, (c) energy packet number, (d) average percentage error.

895 model, each node tries to estimate the amount of
 896 energy it will spend in the near future and it sends
 897 this information, along with its available energy,
 898 to the monitoring node. Simulations were con-
 899 ducted in order to compare the performance of a
 900 prediction-based approach with a naive one, in
 901 which only the available energy is sent to the mon-
 902 itoring node. Simulation results indicate that the
 903 prediction-based approach analyzed is more en-
 904 ergy-efficient than the naive solution, and also that
 905 this approach is more scalable with respect to the
 906 number of sensing events. We also analyzed the
 907 use of a sampling technique to reduce the number
 908 of packets needed to construct the map. Results
 909 showed that its most important advantage is to
 910 produce more constant error curves.

911 The next step is to apply the energy map in
 912 problems such as the trajectory based forwarding
 913 protocol proposed in [5]. The information pre-
 914 sented in the energy map could be used to plan
 915 the trajectory according to energy reserves, pre-
 916 serving or avoiding regions with small energy re-
 917 serves. We also plan to study the construction of
 918 localized energy maps. In all energy map construc-
 919 tions presented in this work, the map of the entire
 920 network was constructed in the monitoring node.
 921 However, in some situations, it is enough to know
 922 the energy information of a neighboring region.
 923 An energy map that gives information about a re-
 924 gion surrounding the node is named localized en-
 925 ergy map. This localized energy information can
 926 be useful to improve the energy efficiency of other
 927 algorithms such as routing protocols. The con-
 928 struction of localized energy map is a promising
 929 extension of this work.

Raquel A.F. Mini holds a B.Sc., M.Sc. and Ph.D. in Computer Science from Federal University of Minas Gerais (UFMG), Brazil. Currently she is an Associate Professor of Computer Science at PUC Minas, Brazil. Her main research areas are sensor networks, distributed algorithms, and mobile computing.

Antonio A.F. Loureiro holds a B.Sc. and a M.Sc. in Computer Science, both from the Federal University of Minas Gerais (UFMG), and a Ph.D. in Computer Science from the University of British Columbia, Canada. Currently he is an Associate Professor of Computer Science at UFMG. His main research areas are wireless sensor networks, mobile computing, distributed algorithms, and network management.

Max do Val Machado received the B.S. degree in Computer Science From Pontifical Catholic University of Minas Gerais, Brazil in 2002. Currently, he is a Master's student in Computer Science at the Federal University of Minas Gerais, Brazil. His research interests are algorithms for wireless sensor networks and mobile ad hoc networks.

Badri Nath is a professor of computer science at Rutgers University. His research interests are in the area of mobile computing and sensor networks. As part of his research, he is developing protocols and services suited for large scale dense networks. His current focus is on developing protocols and services for an information architecture on top of sensor networks. In particular, he is investigating new paradigms for routing, localization, and data management in sensor networks. He is also the recipient of the 10 year best paper award at VLDB-2002. He has served on several program committees of conferences in the area of mobile computing, data management and sensor networks. Currently, he serves on the editorial board of ACM Transactions on Sensor Networks, WINET, Wireless Communications and Mobile computing, and IEEE pervasive computing. He has a Ph.D. from the University of Massachusetts, Amherst.
